Abstract

In many decentralised markets, the traders who benefit most from an exchange do not employ intermediaries even though they could easily afford them. At the same time, employing intermediaries is not worthwhile for traders who benefit little from trade. Together, these decisions amount to non-monotone participation choices in intermediation: only traders of middle “type” employ intermediaries, while the rest, the high and the low types, prefer to search for a trading partner directly. We provide a theoretical foundation for this, hitherto unexplained, phenomenon. We build a dynamic matching model, where a trader’s equilibrium bargaining share is a convex increasing function of her type. We also show that this is indeed a necessary condition for the existence of non-monotone equilibria.

1 Introduction

In many decentralised markets for heterogeneous goods or services, exchange is aided by intermediaries. Even if trade is feasible and legal without them, intermediaries exist because they increase the realised gains from trade by lowering the traders' search costs and by reducing the extent of mismatch. Nevertheless, not all traders use intermediaries. Traders who stand to gain little from exchange may simply find intermediation too expensive, but one often sees the traders on the two sides of the market who have the highest surplus between them decide to trade in the direct search market – risking severe mismatch and/or incurring high search expenditure – despite the availability of “cheap” intermediation. For example, as the title hints, the most desirable singles do not advertise in “lonely hearts” newspaper columns, nor do they join on-line dating services; also, in many instances, the best jobs are not filled through agencies, the best shops are not in shopping centres, the most exclusive holidays are not on offer in travel agencies and the best properties do not come on the open market.¹ As further examples, some banks do not allow mortgage brokers to offer their products, and some insurers advertise the fact that they are not available on web comparison sites.

Formally, the common feature of the above examples is that the traders' decisions to enter the intermediated (sub)market are non-monotone in type.²

¹But note that very different outcomes can occur in similar markets: for example, on 2 December 2009, the most expensive family residence in London available for sale online had an asking price of \$66 million. The most expensive one in Rome, a market with not too dissimilar supply and demand, was on offer at \$8.7 million, a figure certainly well below the prices paid for residences at upper end of the Roman market. This dichotomy is neatly captured by the multiplicity of equilibria in our model.

²Solid empirical evidence linking types and propensity to use intermediaries is hard to come by. The recent paper by Hitsch et al (2010), briefly discussed in Section 5, hints at some non-monotonicity. In general, however, survey studies of the intermediated marriage market (e.g. Goodwin (1990), Bozon and Heran (1989), Kalmijn and Flap (2001) and Rosenfeld and

While this inefficient outcome is clearly a coordination failure, whether it can be supported by an equilibrium depends on the specific modelling set-up. In this article we investigate the features of a model that delivers such non-monotone entry decisions, and we explore the intuition underlying these equilibria. Given the prevalence of markets where traders have the choice between intermediated or direct trade, it is surprising that only a few of the numerous theoretical articles on intermediated markets allow direct and intermediated trade to co-exist. Gehrig (1993) is the seminal paper in this area: he posits a one-shot random matching market, where the maximisation of overall gains from trade requires matching high valuation buyers with low valuation sellers: efficient matching is negatively assortative. In his equilibrium, buyers and sellers who trade are separated by a “threshold”: buyers (sellers) with valuation below (above) the threshold trade in the direct market, buyers (sellers) with valuation above (below) the threshold trade via the intermediary. Gehrig’s finding that trade is via the intermediary for the matches with the highest surplus is confirmed by Fingleton (1997) who models intermediaries as suppliers of liquidity, in the sense that they buy from the sellers before securing a buyer to sell to. Rather than a flat fee, in Yavaş (1994) the intermediary charges a commission on the gains from trade. A second difference is that Yavaş (1994) is a search, not a matching model. Both modelling assumptions make intermediation the less attractive the higher a type is and thus, quite naturally, he finds a reverse threshold: traders’ participation strategies are monotone in type, but the keener types search directly and the less keen go to the intermediary.

A crucial feature of markets with optional intermediation is that each trader’s willingness to employ the intermediary depends on which traders decide to join Thomas (2010), the well established literature on users of real estate agents (Zumpano et al 1996), and the more limited one on job exchanges (Gregg and Wadsworth 1996) contain very limited information about users’ types. Conversely, comprehensive studies of individual preferences in marriage markets, such as Choo and Siow (2006), do not have information about use of intermediation.

on the other side of the market. In the existing literature, equilibria are “coordination” ones, leading naturally to multiplicity. As mentioned above, all equilibria are similar in nature, characterised by a single threshold, possibly a “reversed” one; in particular, traders’ choices are never non-monotone in equilibrium. This does not tally with the stylised facts motivating our paper. We show here that to explain these observations, it is necessary to eschew the simplified modelling of negotiation between matched traders used by the previous literature, which either studied static models (as discussed above) or assumed a dynamic set-up, but with non-transferable utility (Bloch and Ryder, 2000). In contrast, our model displays a richer dynamic set-up where, crucially, a matched trader’s share of the surplus depends on the disagreement, or continuation, payoffs, and therefore on which equilibrium the market finds itself in.

We consider a two-sided market where the traders’ types are complements: higher types benefit more from trade with higher types than lower types do. At the beginning of the first trading period, each trader chooses whether or not to pay a fixed fee to “join” the intermediary. If they join, they are matched assortatively with those who have joined from the other side. Traders who stay out are randomly matched among those who have stayed out on the other side of the market. Once matched, traders negotiate; crucially, refusing an exchange does not entail the loss of all benefit from trade because all the agents who have not traded can re-enter the market later.³ In this dynamic set-up, the outcome of bargaining is a function of the continuation values of the traders, which in turn depend on their type. We find equilibria with the following features: high quality traders trade in the direct search market, and may suffer a delay in finding a suitable partner; traders with medium quality use the inter-

³Burani (2008) has a similar, fully dynamic set-up; however, for tractability, she needs to restrict attention to two types on each side of the market, ruling out non-monotone equilibria by construction.

mediary, and so trade immediately with probability 1; low quality traders also search directly, even when the price of intermediation is *per se* insufficient to deter them. The middle quality traders who use the intermediary are therefore “sandwiched” between the high and low quality ones who do not, and so we label this a “sandwich equilibrium”.

This seemingly appealing intuition disguises however that for this outcome to emerge as an equilibrium stringent conditions must hold, suggesting therefore that sandwich equilibria have more to them than simple coordination. We show in Proposition 4 that, for a sandwich equilibrium to exist, the traders’ bargaining share must be sufficiently increasing in their own type.⁴ The logic of this requirement can be gleaned by considering the decisions of two types: a high type, H , who does not join the intermediary, and a medium type, M , who does join. In order for H not to want to deviate from her equilibrium strategy and join the intermediary instead, the probability of meeting a low type in the open market must be sufficiently low. Since matching is type-independent, this is true for every trader. That is, any agent who stays out must have a relatively high chance of meeting a high type. Given this, why does M not want to deviate? What stops staying out and perhaps meeting a high type from becoming an alluring prospect for M ? It must be that if M meets H , he receives a low enough share of the surplus. Given the Nash bargaining protocol, this in turn is possible if M has a sufficiently lower continuation value than H .

The paper develops this argument in detail. The model is presented in Section 2, and the results in Section 3. There, in Proposition 3, we show that sandwich equilibria do indeed exist if the continuation value is increasing in type and in Proposition 4 that they do not if the continuation value is the same for all traders. Section 4 discusses the results and reports some numerical simulations, which indicates that the set of sandwich equilibria is

⁴In particular, with non-transferable utility, as assumed by Bloch and Ryder (2000), sandwich equilibria cannot happen.

“large”. Section 5 concludes, relating the analysis to some empirical evidence.

2 The model

2.1 The traders

We study a two-sided market where the participants meet in pairs and share the surplus jointly available to them. For specificity we refer to the two sides as buyers and sellers, but the set-up clearly applies to more general situations, such as the marriage market. Each trader is characterised by a single attribute:⁵ a seller by the quality she offers, denoted by q , and a buyer by the value he places on quality, v . We assume that the (empirical) distribution of attributes on both sides of the market is common knowledge among the traders.⁶

The attributes of matched traders are complements: a high value buyer appreciates a given increase in quality more than a low value buyer. Note that this means that the most efficient matching is the perfectly assortative one (see Becker, 1973). For definiteness, we assume that the joint gross surplus available to the matched pair of a seller of quality q and a buyer of value v is given by $2vq$.

Within a matched pair of traders, utility is transferable and the outcome of negotiation is given by the Nash Bargaining Solution. That is, each trader obtains the sum of (i) the payoff he/she would obtain if trade did not happen – the disagreement payoff –, and (ii) one half of the net surplus from trade. The

⁵In practice traders are differentiated along several, imperfectly correlated dimensions. A model capturing this could generate sandwich equilibria even if behaviour were monotone along each dimension. By compressing the differences among traders along one dimension we “stack the deck” against sandwich equilibria, giving more robustness to our analysis.

⁶The role of this assumption, which simplifies the analysis, is to ensure that in equilibrium the traders can predict with certainty whether or not they will be matched with a given group of traders on the other side of the market.

latter is given by the difference between the gross surplus and the sum of the parties' disagreement payoffs. If it is negative, no trade takes place.

The nature of the disagreement payoff, that is whether it is fixed or type dependent, affects the equilibrium set greatly. In a static set-up, there is no future and so the status quo payoff is fixed at 0. As we show below, in this case it is impossible to capture the empirical regularities mentioned in the introduction. In order to endogenise the disagreement payoff, we build a simple dynamic model.

Time is divided in periods. At the beginning of the first period, traders on both sides of the market simultaneously choose whether they wish to participate in the direct market or to employ the intermediary. Their choices create two submarkets: the intermediated and the direct market. The direct market is anonymous: each trader on the same side has identical expectations about whether she will find a match and in case yes, who with. Joint rationality of these expectations implies that, in equilibrium, the likelihood of meeting a given type must be proportional to the empirical type distribution. We assume that the matching technology is efficient: all the traders on the short side get matched to someone on the long side. If the matched traders trade, they leave the market. If they do not trade, they stay in the market, and will be matched again in the second period. All unmatched traders continue in the market as well. There is no entry of new traders. The continuation payoff of the traders who return to the market after the first period satisfies the following condition.

Assumption 1 *The present value of trading in the future equals a proportion $\lambda \in (0, 1)$ of the utility a trader would receive if in the second period he/she were perfectly assortatively matched among the remaining traders and shared the gross surplus equally.*

Assumption 1 can be relaxed, its important feature is that a trader's continuation payoff increases sufficiently with his/her type, which we show to be

crucial to establish the existence of sandwich equilibria. Notice that the continuation payoff depends on the other traders' period 1 choices: a trader's chances tomorrow depend on who is not trading today, and will therefore be still around tomorrow.

λ is a measure of the cost of delaying trade. For example, if, in the second period, all traders who have not traded in the first period were indeed matched assortatively, say by a free intermediary, then λ would simply be the discount factor.⁷ Alternatively, Assumption 1 holds if traders use hyperbolic discounting, whereby the discounted present value of a reward W in period $t > 0$ is given by $\lambda\gamma^t W$, with $\gamma \cong 1$. This means that traders believe that they will become infinitely patient from the next period onwards, and therefore believe that they will be willing to wait indefinitely for the perfect match, leading to the efficient assortative matching.⁸

2.2 The intermediary

The simplest form of intermediation is one where the intermediary selects as “members”, through price or other means, only a subset of traders from both sides of the market (see, for example, Damiano and Li, 2007), and subsequently matches its members randomly. This merely ensures that members meet with members only, but already reduces mismatch. In practice, intermediaries, from

⁷Given assortative matching in the second period, no unmatched traders are left in the market beyond it, and so it is irrelevant whether or not the game continues after period 2.

⁸Note that our set-up satisfies the sufficient conditions proposed by Shimer and Smith (2000) for assortative matching in a dynamic search equilibrium. Damiano et al. (2005) imply that such a dynamic matching model would unravel and lead to pooling instead of assortative matching. However, their result depends crucially on the assumption of a per period fixed cost of participation. With discounting only, as in our model, assortative matching is the limit for infinitely patient players. Lu and McAfee (1996) use simulations to establish this in a closely related model without intermediation.

tour operators through online dating services to wholesalers of grain and tea,⁹ make very good use of their understanding of their members' characteristics to improve the efficiency of matches, by arranging the traders into fine clusters and restricting matches to within each cluster. This practice approximates assortative matching, and, for the sake of simplicity, we take it to the extreme and assume that the intermediary has access to a costless, perfectly assortative matching technology.¹⁰ Thus the intermediary will match the highest members from each side of the markets, the two second highest ones, and so on. The low ranked members on the long side will remain unmatched, and try their luck in the second period. For ease of exposition, we work with a continuum of traders. Taking it literally, this would imply that if in equilibrium the same measure of traders joined the intermediary on the two sides of the market then a deviating trader who was not supposed to join in equilibrium would still get matched if he joined, as the measure of traders joining would still be equal on the two sides. This would be unsatisfactory, as a repeated use of the assumption would lead to a paradox, in a similar fashion to the generation of thick indifference curves. Our preferred way to solve this problem is to view the case of the continuum as the limit case of a model with a finite number of traders. In a finite set-up, if in equilibrium the same number of traders joined then a deviating one (with a low valuation) would be the lowest on the long side and hence would not be matched. To retain the logic of the finite set-up in the continuum case, we assume that, when the same measure of traders on the two sides join the intermediary, an additional trader with type lower than all those who have joined the intermediary on his side of the market would remain unmatched.

⁹See for example, Clerides et al. (2008), Hirsch et al (2010) Gabre-Mahdin (2001) and Koo and Lo (2004), respectively. Biglaiser (1993) gives a theoretical treatment.

¹⁰In related contexts it has been shown that the loss of efficiency from a "coarse" relative to a "fine" clustering is very low and, consequently, perfect assortative matching is not a particularly strong assumption: see McAfee (2002) and Hoppe et al. (2008).

Joining the intermediary¹¹ entails paying an exogenously given fee $c \geq 0$, which is the same for all traders.¹²

We end this Section with a summary of the extensive form of the game.

1. At the beginning of Period 1 all traders observe the distribution of attributes in the market and then simultaneously decide whether to join the intermediary and pay the joining fee $c \geq 0$, or to trade in the direct market.
2. Matching takes place in the two separate submarkets. Matching in the direct market is random, with the intermediary is assortative. If the joiners are of equal measure, then a deviating trader with a valuation below the minimum for joining in equilibrium will remain unmatched. Matched traders observe each other's type and, if and only if their joint surplus is non-negative, they trade according to the Nash Bargaining Solution. Buyers and sellers who trade leave the game.
3. In Period 2 the remaining traders are matched assortatively and once they have observed each other's type they trade according to the Nash Bargaining Solution (with zero status quo payoffs). Seen from Period 1, the payoffs from agreements in Period 2 are discounted by λ .

¹¹As will become apparent, our model is equivalent to a situation where the intermediary's fee is paid only by the traders who are matched.

¹²Notice how our model could be reinterpreted as a special case of two-sided markets, where traders are restricted to trade via "platforms". One platform is direct trade, the other is the intermediary. The former has lower efficiency and an exogenously given zero fee. To our knowledge, such a set-up has not been analysed in this literature. The most closely related papers are Armstrong (2006), Caillaud and Jullien (2003), Damiano and Li (2007, 2008) and Rochet and Tirole (2003).

3 Equilibrium analysis

3.1 A simple finite market

We begin with a simple example. While our interest is in the study of large anonymous markets, and so the more natural set-up is with a continuum of traders, considering first a finite market highlights the intuition underlying our results and assumptions. Suppose therefore that we have n buyers and n sellers, with the sets of types, $\{v_1, \dots, v_n\}$ and $\{q_1, \dots, q_n\}$, where $v_i \leq v_{i+1}$, and $q_i \leq q_{i+1}$ $i = 1, \dots, n - 1$. Consider the following strategy vector: traders $\{v_1, v_n\}$ and $\{q_1, q_n\}$ stay in the market and all other traders join the intermediary. For suitable parameter values, this is an equilibrium. We show this with several simplifying assumptions, and the reader should bear in mind that the restrictions they imply are sufficient, but not necessary for the existence of sandwich equilibria.

In order for the above strategy profile to be an equilibrium, no type can have an incentive to deviate: Consider the highest type, v_n , first. Suppose that

$$\lambda > \frac{2q_1v_n}{q_nv_n + q_1v_1}. \quad (1)$$

If (1) holds, type v_n will not trade if matched with the lowest type q_1 .¹³ It follows that v_n 's expected payoff if he stays in the market is $\frac{1+\lambda}{2}v_nq_n$: if he is not matched with type q_n initially, he will in period 2, since q_n (who is matched to v_1) by the mirror image of (1) will also refuse to trade. If type v_n deviates and joins the intermediary, he will be matched to type q_{n-1} . To calculate his payoff, we need to work out his reservation payoffs in this match, and to do so we need to consider what happens in the event of a break-down in their (v_n and q_{n-1}) negotiations. Given the deviation, there is one buyer (type v_1) and two sellers (q_n and q_1) in the open market in period 1. This implies that:

¹³When v_n and q_1 are matched, their respective reservation utilities are $\lambda q_n v_n$ and $\lambda q_1 v_1$, and so the surplus is $2q_1v_n - \lambda q_n v_n - \lambda q_1 v_1$. Trade does not occur if this surplus is negative, which gives the condition on λ .

- with probability $\frac{1}{2}$, v_1 and q_1 are matched and trade, and in period 2 there is only buyer q_n and seller v_2 (who cannot find a match through the intermediary). Therefore, in the event of a break-down in the negotiation for the pair $\langle v_n, q_{n-1} \rangle$, the period 2 market would be $\{\{v_n, v_2\}, \{q_n, q_{n-1}\}\}$.
- with probability $\frac{1}{2}$ v_1 is matched to q_n , and they do not trade but return to the market in period 2, and q_1 is unmatched. So in the event of a break-down in the negotiation for the pair $\langle v_n, q_{n-1} \rangle$, the period 2 market would be $\{\{v_n, v_2, v_1\}, \{q_n, q_{n-1}, q_1\}\}$.

In either of these cases, in period 2 v_n will be matched to q_n , and his period 1 partner, q_{n-1} , will be matched to v_2 . To sum up, v_n 's deviation payoff is $\lambda v_n q_n + \left(\frac{1}{2}(2v_n q_{n-1} - \lambda v_n q_n - \lambda q_{n-1} v_2)\right) - c$, if the surplus from trade, the term in the brackets, is non negative, which is the case if

$$\lambda \leq \frac{2v_n q_{n-1}}{v_n q_n + q_{n-1} v_2} \quad (2)$$

If we assume the above to hold, then the difference between the equilibrium and the deviation payoff for type v_n is:

$$\frac{\lambda q_{n-1} v_2}{2} + v_n \left(\frac{1}{2} q_n - q_{n-1} \right) + c \quad (3)$$

Next consider a type who uses the intermediary in equilibrium, call him v_i . His equilibrium payoff is $v_i q_i - c$. Suppose he contemplates a deviation. He will find himself in a market where there are three types on his side, $\{v_1, v_i, v_n\}$, and two types on the other side $\{q_1, q_n\}$. In the next period, q_2 will be there, plus the unmatched v type, and whoever has failed to trade. So we have three possible outcomes, each with probability $\frac{1}{3}$.

- v_i is unmatched. In the following period, either the market is $\{\{v_i\}, \{q_2\}\}$, because period 1 matching was assortative, or it is $\{\{v_n, v_i, v_1\}, \{q_n, q_2, q_1\}\}$, if q_1 was matched to v_n . In both cases, v_i will be matched to q_2 in period 2, so his deviation payoff in this case is $\lambda v_i q_2$.

- v_i is matched to type q_1 . Either v_1 is unmatched, and q_n and v_n trade with each other, so the next period market, in the case of a break-down in the $\{v_i, q_1\}$ negotiation is $\{\{v_i, v_1\}, \{q_2, q_1\}\}$, or v_n is unmatched, and q_n and v_1 do not trade, so the next period market is $\{\{v_n, v_i, v_1\}, \{q_n, q_2, q_1\}\}$. In both cases, v_i is matched in the second period to q_2 , and so the reservation payoff for the traders is $\lambda v_i q_2$ for v_i and $\lambda v_1 q_1$ for q_1 . So the deviation payoff for trader v_i is $\lambda v_i q_2 + \max\{\frac{1}{2}(2v_i q_1 - \lambda v_i q_2 - \lambda v_1 q_1), 0\} = \frac{1}{2}(2v_i q_1 + \lambda v_i q_2 - \lambda v_1 q_1)$, if

$$\lambda < 2 \frac{v_i q_1}{v_i q_2 + v_1 q_1}, \quad i = 2, \dots, n-1. \quad (4)$$

- v_i is matched to type q_n . Again there are two cases, the unmatched buyer can be either v_1 or v_n . If v_1 is unmatched, q_n and v_n trade with each other, and the remaining match $\langle q_1, v_n \rangle$ does not lead to trade, so the next period market, in the case of a break-down in the $\langle v_i, q_n \rangle$ negotiation is $\{\{v_n, v_i, v_1\}, \{q_n, q_2, q_1\}\}$. If instead v_n is unmatched, then the post break-down market is $\{\{v_n, v_i\}, \{q_n, q_2\}\}$. Again, in both these cases v_i will be matched to q_2 , so her period 2 payoff is $\frac{1}{2}(2v_i q_n + \lambda v_i q_2 - \lambda v_n q_n)$.

Putting the above three observations together the difference between equilibrium and deviation payoff of player v_i is

$$\frac{2v_i(3q_i - q_1 - q_n) - \lambda(4v_i q_2 - v_1 q_1 - v_n q_n)}{6} - c \quad (5)$$

Finally, the lowest type buyer, v_1 , would certainly be unmatched if he joined the intermediary, so deviating only (possibly) delays his trade with q_1 , in expectation lowering his payoff. If (1), (2) and (4) (and their mirror images for the other side of the market) hold, and both (3) and (5) (and their mirror counterparts) are non-negative, then this combination of strategies is an equilibrium. As an example,¹⁴ this happens if $\lambda = 0.8$, $c = 0.014$, and the two sides of the

¹⁴The calculations are available at sites.google.com/site/giannidefraja/.

market have types $\{0.98, 0.6, \dots, 0.48, 0.32\}$ and $\{0.97, 0.55, \dots, 0.45, 0.28\}$ and any combination of types for the traders ranked $3, \dots, n-2$: they join the intermediary and all trade with their match, since (4) holds for every $i = 2, \dots, n-1$. It is relatively straightforward, though it becomes notationally complex very rapidly, to add traders at the top and at the bottom of the type distribution, who do not join the intermediary, and so to obtain equilibria where more than four traders use the direct market.

Though simple, the example illustrates an important feature of sandwich equilibria: the continuation payoffs, following deviations, of type v_n and of type v_{n-1} are radically different. The reason is that type v_n , if instead of following the equilibrium strategy, deviates and joins the intermediary to be matched with q_{n-1} will have a very strong hand in the negotiation, because, in the next period, q_{n-1} would be matched to the lowest type among those who have joined the intermediary, v_2 : and so, when matched to q_{n-1} , v_n will have the lion's share of their joint surplus. If however v_{n-1} were to deviate and join the market, he would, by the same argument, have a very weak hand in a negotiation with the top type, q_n (which of course happens with probability less than 1, as there is also trader q_1 in the market). So there is a discontinuity, determined by the difference in the bargaining strength, which in turn depends on the dynamic nature of game, between the payoffs of the lower type in the top group of traders in the market, who will be matched with a trader in the same group, and the top trader in the intermediary, who will be matched to the least desirable trader among those who join the intermediary in period 1.

3.2 A continuum of traders

We now consider the general case, where there are a continuum of risk neutral traders – of equal measure – on each side of the market. The buyers' values and the sellers' qualities are distributed according to strictly positive density functions $f_B(v)$ and $f_S(q)$ in $[0, 1]$. We have seen in the previous section

that the distribution of attributes need not be symmetric for the existence of a sandwich equilibrium. Nonetheless, for simplicity we assume henceforth that $f_B(t) = f_S(t)$ for every $t \in [0, 1]$. Therefore, we can refer to a generic trader's type as $t \in [0, 1]$, with values distributed according to the strictly positive function $f(t)$. We also define $F(t) = \int_0^t f(x) dx$, which we normalise by $F(1) = 1$.¹⁵ We begin by calculating the payoffs in the case where the joining decisions mirror each other on the two sides of the market. Let A be the set of types that do not join the intermediary, and let $\mu(A)$ denote the measure of this set.

Proposition 1 *If the set of types that join the intermediary is the same on both sides, then the payoff of a trader of type $t \in [0, 1]$ is*

$$t^2 - c, \tag{6}$$

if he/she joins the intermediary, and

$$\lambda t^2 + \frac{\int_A \max \left\{ tq - \frac{\lambda}{2} (q^2 + t^2), 0 \right\} f(q) dq}{\mu(A)}, \tag{7}$$

if he/she does not join.

Proof. (6) is obvious: since the intermediary matches the members assortatively, and since the n -th ranked type that joins the intermediary is the same on both sides of the market, type t is matched with type t and they trade immediately. By doing so, they obtain payoff $t^2 - c$, because, since they have the same outside option, they share the gross surplus equally, from which the joining fee is subtracted. Consider next (7), the payoff for not joining the intermediary. This is simply the weighted average payoff of all possible matches. The probability of a match with type q is $\frac{f(q)}{\mu(A)}$. The payoff to type t following a match with type q is $\max \left\{ tq - \frac{\lambda}{2} (q^2 + t^2), 0 \right\}$. To show this, note

¹⁵Note that the type distributions are deterministic, while in the direct market the traders (rational) belief is that the relative likelihood that they are matched to type p rather than type q is given by $\frac{p}{q}$. This set-up avoids possible complications that might arise with defining a random matching process with a continuum of traders (see, for example, Alos-Ferrer, 1999).

that in equilibrium, the continuation payoff of a type t trader is λt^2 . This is the case because, in period 2, the type distribution is the same on the two sides of the market: in the first period symmetry holds by assumption and, by the law of large numbers, the distribution of “leavers” is also the same on both sides. Therefore, trade between t and q occurs in the first period if and only if they obtain a non-negative surplus from trading, that is if $2tq - \lambda(q^2 + t^2) \geq 0$, and (7) follows. ■

Based on the proof of Proposition 1, Corollary 1 identifies which matches lead to trade.

Corollary 1 *If the set of types that join the intermediary is the same on both sides, a type v trader trades with a type q trader in the first period if and only if $q \in \left[\frac{1-\sqrt{1-\lambda^2}}{\lambda}v, \frac{1+\sqrt{1-\lambda^2}}{\lambda}v \right]$.*

Figure 1 illustrates this: trade occurs only if the matched traders’ type vector is in the grey area. Notice that, since $\lambda \rightarrow 1$ implies $\frac{1-\sqrt{1-\lambda^2}}{\lambda} \rightarrow 1$, as λ increases, the grey area shrinks to the diagonal: if traders are infinitely patient, they are unwilling to “trade down” and matching must be assortative. Vice versa, if $\lambda \rightarrow 0$, we have $\frac{1-\sqrt{1-\lambda^2}}{\lambda} \rightarrow 0$, and the grey area tends to the whole square $[0, 1]^2$: if waiting becomes infinitely costly then any match leads to trade as the gross surplus is non-negative.

As mentioned in the introduction, the equilibria derived in the existing literature stratify the types into two groups. Definition 1 captures this idea.

Definition 1 *A t -threshold equilibrium is a SPE with the property that all traders with type greater than or equal to t join the intermediary.*

As one would expect, our model exhibits a rich multiplicity of threshold equilibria, as the following proposition shows. Let $r = \frac{1-\sqrt{1-\lambda^2}}{\lambda}$ and $\sigma(\lambda) = \lambda + \int_r^1 \left(q - \frac{\lambda}{2}(q^2 + 1) \right) f(q) dq$. Note that $\sigma(\lambda) \in [0, 1]$, with $\sigma(1) = 1$.

Proposition 2 *For every joining fee $c \in [0, 1 - \sigma(\lambda))$, there exists $x(c) \in [0, 1)$ such that a t -threshold equilibrium exists for every $t \in [x(c), 1]$.*

Figure 1: The set of matched pairs who agree to trade.

Proof. Fix a putative t -threshold equilibrium. By Proposition 1, types $v \geq t$ expect a payoff of $v^2 - c$ in equilibrium, whereas deviating implies an expected payoff of $\lambda v^2 + \frac{\int_0^t \max\{vq - \frac{\lambda}{2}(q^2 + v^2), 0\} f(q) dq}{F(t)}$ which, by Corollary 1, equals $\lambda v^2 + \frac{\int_{vr}^t (vq - \frac{\lambda}{2}(q^2 + v^2)) f(q) dq}{F(t)}$. Let $D(t, v)$ be the difference between the equilibrium and deviation payoffs for type $v \geq t$. We start with establishing that $D(t, v)$ is increasing in v , so that it is sufficient to check incentive compatibility for the threshold type, $v = t$.

$$\begin{aligned} \frac{\partial D(t, v)}{\partial v} &= 2v(1 - \lambda) - \int_{vr}^t \frac{(q - \lambda v) f(q)}{F(t)} dq + \frac{r(v^2 r - \frac{\lambda}{2}(r^2 v^2 + v^2)) f(vr)}{F(t)} \\ &\geq 2t(1 - \lambda) - \int_{vr}^t \frac{(t - \lambda t) f(q)}{F(t)} dq = t(1 - \lambda) \left(1 + \frac{F(vr)}{F(t)}\right) \geq 0. \end{aligned}$$

Here the first inequality follows from the fact that $v \geq t \geq q$ and that the last term is 0, as the lower bound of the integral is by definition the value of q for which the integrand is 0.

Next, observe that $D(1, 1) = 1 - c - \sigma(\lambda)$. As the integrand in $\sigma(\lambda)$ is strictly increasing, we obtain a strict upper bound on $\sigma(\lambda)$ by setting $q = 1$ in the integrand: $\sigma(\lambda) < \lambda + (1 - \lambda)(1 - F(r)) < 1$. Hence, $1 - \sigma(\lambda) > 0$, so for $c \in [0, 1 - \sigma(\lambda))$, $D(1, 1) > 0$.

Then, by the continuity of the function $D(t, t)$ in t , for any $c \in [0, 1 - \sigma(\lambda))$ there exists a type $x(c) < 1$, such that for all $v > x(c)$, we have $D(v, v) > 0$.

Finally, consider types $v < t$. Their equilibrium payoff is at least λv^2 , while their deviation payoff is $\lambda v^2 - c$, since, given that they are the lowest type on the long side of the intermediated sub-market, they would remain unmatched with the intermediary. Hence deviation is not profitable. ■

When intermediation is free, a more precise characterisation is possible: $x(0) = 0$.

Corollary 2 *When $c = 0$ there is a threshold equilibrium for every $t \in [0, 1]$.*

Proof. Take any $t \geq 0$. We show that there exists a t -threshold equilibrium, which establishes the result. Consider first types below t : in the second period they are assortatively matched, and so their period 1 reservation payoff is the same in equilibrium and following a deviation. However, they trade with zero probability in period 1 if they deviate (the intermediary will not match them), and with non-zero probability in equilibrium. Therefore, it is preferable for them to follow their putative equilibrium strategy and stay out. Consider now a type $v \geq t$. If she follows the equilibrium strategy, she is matched by the intermediary to type v , trades, and obtains a payoff of v^2 . If she deviates, she is matched to type $q < t$, which gives her a payoff of λv^2 if she does not trade and $\lambda v^2 + vq - \frac{\lambda}{2}(v^2 + q^2)$ if she trades. Since the last expression is strictly increasing in q for $q < v$ and equals v^2 when $q = v$, it is no more than v^2 for $q \leq v$, and so type v does not gain by deviating from her putative equilibrium strategy. This shows that no-one has an incentive to deviate and so there is a t -threshold equilibrium. ■

Hence, for any $\lambda \in [0, 1]$, there exists a 0-threshold equilibrium if and only if $c = 0$. In words, with no intermediation fee, and only with no intermediation fee, it is an equilibrium for all traders to join, which is the efficient outcome, given our assumption that the intermediary can sort costlessly.

Threshold equilibria are identified in the existing literature, and have a natural explanation: the top traders join a club, which, although open to all

who are willing to pay the fee, has little use for those whose valuation and quality is below the threshold, as they will be cold-shouldered by the members. This is a straightforward “coordination” explanation, each trader wants to do whatever his or her “natural” partner does, highlighted sharply in the extreme case of free intermediation, when any type $t \in [0, 1]$ can be the threshold in a t -threshold. As we see below, a coordination explanation is not sufficient for the emergence of sandwich equilibria.

But this natural equilibrium configuration is not the only possible one in our dynamic setting. We show next that there are equilibria where only traders with intermediate types join the intermediary, while “top” and “bottom” type traders search directly.

Definition 2 *A $\{\underline{t}, \bar{t}\}$ -sandwich equilibrium with $0 \leq \underline{t} < \bar{t} < 1$ is a SPE, where in period 1 a trader joins the intermediary if and only if he/she has type $t \in [\underline{t}, \bar{t}]$. If $0 < \underline{t}$, the sandwich equilibrium is non-degenerate.*

The following lemma, which we need in the proof of our main result, is of independent interest.

Lemma 1 *In a $\{\underline{t}, \bar{t}\}$ -sandwich equilibrium, the deviation payoff of a type t trader is given by:*

$$\lambda t^2 - c \quad \text{for } t \in [0, \underline{t}], \quad (8)$$

$$\lambda t \underline{t} + \frac{\int_{[0, \underline{t}] \cup (\bar{t}, 1]} \max \left\{ tq - \frac{\lambda}{2} (q^2 + t \underline{t}), 0 \right\} f(q) dq}{1 - F(\bar{t}) + F(\underline{t})} \quad \text{for } t \in [\underline{t}, \bar{t}], \quad (9)$$

$$\lambda t^2 + \max \left\{ t \bar{t} - \frac{\lambda}{2} (t^2 + \bar{t}^2), 0 \right\} - c \quad \text{for } t \in (\bar{t}, 1]. \quad (10)$$

Proof. If a low type ($t \in [0, \underline{t})$) deviates and joins the intermediary, she pays the joining fee c , does not trade, and is assortatively matched in the next period. Her payoff is therefore $\lambda t^2 - c$.

Consider a middle type next: $t \in [\underline{t}, \bar{t}]$. Her deviation payoff is determined by the Nash bargaining solution and it is a function of her continuation value, which is $\lambda t \underline{t}$.

To see this, note that, following a deviation, a seller of type q is either matched to a high type (with probability $\frac{1-F(\bar{t})}{1-F(\bar{t})+F(\underline{t})}$) or matched to a low type (with probability $\frac{F(\underline{t})}{1-F(\bar{t})+F(\underline{t})}$). In both cases, all the top buyers who reach period 2 will be matched with a seller of type equal to their own, and therefore, a deviating type q seller will be matched to the highest type who is left in the market after all the top buyers are assortatively matched, which is \underline{t} .

Finally, consider a high type buyer, $v \in (\bar{t}, 1]$. If he decides to join the intermediary, he will participate in an assortative matching, where he is the highest type. Consequently, he will be matched with the highest type seller who joins the intermediary in equilibrium, $q = \bar{t}$. This gives his deviation payoff (10), and establishes Lemma 1. ■

The proof hinges on the comparison between equilibrium and deviation payoffs. Of the latter, (8) and (10) in Lemma 1 are relatively straightforward, (9) less so. To evaluate it, it is necessary to determine whether a type $t \in [\underline{t}, \bar{t}]$, who should join the intermediary in equilibrium, would trade in the first period, if he/she deviated instead and were matched in the direct market. To proceed, compact notation by writing $(tq - \frac{\lambda}{2}(q^2 + \underline{t}t)) f(q)$ as $h(q, \underline{t}, t)$, and $\frac{1-\sqrt{1-\lambda^2(\underline{t}/t)}}{\lambda}$ as $R(\underline{t}/t)$, and write (9) as:

$$\frac{\int_{\underline{t}R(\underline{t}/t)}^{\underline{t}} h(q, \underline{t}, t) dq}{1 - F(\bar{t}) + F(\underline{t})} + \lambda \underline{t} \quad \text{for } t \in \left(\underline{t}, \frac{\lambda \bar{t}^2}{2\bar{t} - \lambda \underline{t}} \right), \quad (11)$$

$$\frac{\int_{\underline{t}R(\underline{t}/t)}^{\underline{t}} h(q, \underline{t}, t) dq}{1 - F(\bar{t}) + F(\underline{t})} + \frac{\int_{\bar{t}}^{\underline{t}R(\underline{t}/t)} h(q, \underline{t}, t) dq}{1 - F(\bar{t}) + F(\underline{t})} + \lambda \underline{t} \quad \text{for } t \in \left[\frac{\lambda \bar{t}^2}{2\bar{t} - \lambda \underline{t}}, \frac{\lambda}{2 - \lambda \underline{t}} \right], \quad (12)$$

$$\frac{\int_{\underline{t}R(\underline{t}/t)}^{\underline{t}} h(q, \underline{t}, t) dq}{1 - F(\bar{t}) + F(\underline{t})} + \frac{\int_{\underline{t}}^1 h(q, \underline{t}, t) dq}{1 - F(\bar{t}) + F(\underline{t})} + \lambda \underline{t} \quad \text{for } t \in \left(\frac{\lambda}{2 - \lambda \underline{t}}, \bar{t} \right]. \quad (13)$$

Figure ?? illustrates this. The coloured subset in the diagram depicts the combinations of types (v, q) such that if a type $v \in [\underline{t}, \bar{t}]$ deviates and is matched to type $q \in [0, \underline{t}) \cup (\bar{t}, 1]$, then trade occurs. These points are those above and to the right of the locus determined by the two curves $q = \frac{v - \sqrt{v^2 - \lambda^2 v \underline{t}}}{\lambda}$ and

$q = \frac{v + \sqrt{v^2 - \lambda^2 v t}}{\lambda}$. This locus intersects the line t at $v = \frac{\lambda t}{2 - \lambda}$; it also intersects the diagonal at $v = \frac{\lambda t}{2 - \lambda}$. It reaches its leftmost point (a minimum on the vertical axis) at point $(v = \lambda^2 t, q = \lambda t)$, and it has a horizontal asymptote at $q = \frac{\lambda}{2} t$. Finally, it intersects the line $q = 1$ at $v = \frac{\lambda}{2 - \lambda t}$, and the line $\frac{v}{\lambda} (1 - \sqrt{1 - \lambda^2})$ at $v = t$.

A further noteworthy feature illustrated in Lemma 1 is the dependence of traders' continuation payoff on the first period actions of the other traders. For example, a trader of type $t \in [t, \bar{t}]$ contemplating a deviation has a no trade payoff given by $\lambda t t$, since we have assumed the second period matching to be perfectly assortative. This captures the idea that an "intermediate" type trader needs to take into account the fact that tomorrow, he will likely be "mismatched", given that his natural partner – the types similar to his – will be rare, as they have traded today through the intermediary. This likely mismatch will be understood and exploited by his period 1 match, and so deviating from the equilibrium strategy reduces a trader's current bargaining power.

We are now ready to present our main result.

Proposition 3 *If the density of the distribution of attributes $f(t)$ is Lipschitz*

continuous at 0, then for any $\lambda > \frac{1}{2}$, there exists $c^* > 0$ such that, for every $c \in [0, c^*]$, there exists a non-degenerate $\{\underline{t}, \bar{t}\}$ -sandwich equilibrium.

Proof. We begin by considering the special case of a degenerate sandwich equilibrium, $\underline{t} = 0$, and no entry fee, $c = 0$. Our argument will be based on the concept of $\{\underline{t}, \bar{t}\}$ -almost strict sandwich equilibrium, $\{\underline{t}, \bar{t}\}$ -ASSE for short. This is a $\{\underline{t}, \bar{t}\}$ -sandwich equilibrium where all traders, with the exception of trader $t = 0$, *strictly* prefer to follow their equilibrium strategy rather than deviate; trader $t = 0$ is indifferent. We first show that there are $\{0, \bar{t}\}$ -ASSE's. Next we establish the existence of a $\{\varepsilon, \bar{t}\}$ -ASSE: it is possible to increase the lower bound of the set of “joiners” slightly above 0, to some $\varepsilon > 0$, and maintain the property that all traders, including traders in $(0, \varepsilon]$, *strictly* prefer to follow their equilibrium strategy rather than to deviate. This establishes the proposition for the special case $c = 0$. Since all traders who join the intermediary *strictly* prefer to do so, it is possible to choose a positive c such that this continues to be the case, establishing the Proposition.

To begin, therefore, we first want to show that, for some $\bar{t} \in (0, 1)$, when $\underline{t} = 0$ and $c = 0$, the types in $(0, \bar{t})$ (the “degenerate” middle) prefer to join the intermediary and the types above \bar{t} prefer not to. Formally:

$$t^2 > \frac{\int_{(\bar{t}, 1]} \max \left\{ tq - \frac{\lambda}{2} q^2, 0 \right\} f(q) dq}{1 - F(\bar{t})} \quad \text{for } t \in (0, \bar{t}], \quad (14)$$

$$\frac{\int_{(\bar{t}, 1]} \max \left\{ tq - \frac{\lambda}{2} (q^2 + t^2), 0 \right\} f(q) dq}{1 - F(\bar{t})} > \max \left\{ t\bar{t} - \frac{\lambda}{2} (t^2 + \bar{t}^2), 0 \right\} \quad \text{for } t \in [\bar{t}, 1]. \quad (15)$$

To ensure almost strictness, we require that both (14) and (15) be satisfied at \bar{t} . Take constraint (15), and evaluate it for the marginal type, $t = \bar{t}$. We need to show that

$$\frac{\int_{(\bar{t}, 1]} \max \left\{ \bar{t}q - \frac{\lambda}{2} (q^2 + \bar{t}^2), 0 \right\} f(q) dq}{1 - F(\bar{t})} > (1 - \lambda) \bar{t}^2.$$

This is implied by

$$\frac{\int_{(\bar{t}, 1]} (\bar{t}q - \frac{\lambda}{2} q^2) f(q) dq}{1 - F(\bar{t})} > \left(1 - \frac{\lambda}{2}\right) \bar{t}^2. \quad (16)$$

Note that the LHS in (16) is the average value of the function $g(q) = \bar{t}q - \frac{\lambda}{2}q^2$ in the interval $[\bar{t}, 1]$, while the RHS is $g(\bar{t})$. $g(q)$ is a negative quadratic and hence it reaches its minimum on $[\bar{t}, 1]$ either at \bar{t} or at 1. Consequently, a sufficient condition for the strict inequality to hold is that $g(\bar{t}) = \bar{t}^2(1 - \frac{\lambda}{2}) \leq \bar{t} - \frac{\lambda}{2} = g(1)$. This is equivalent to $\bar{t} \in [\frac{\lambda}{2-\lambda}, 1]$, which is non-empty for all $\lambda \in (0, 1)$. Next, we show that if the inequality is satisfied for the marginal type, $t = \bar{t}$, it is also satisfied for all types $t > \bar{t}$. Note first that whenever $tq - \frac{\lambda}{2}(q^2 + t^2) > t\bar{t} - \frac{\lambda}{2}(t^2 + \bar{t}^2)$ for every t , it is also true that $q \in [\bar{t}, 1]$, and therefore (15) is implied by

$$\frac{\int_{[\bar{t}, 1]} (tq - \frac{\lambda}{2}(q^2 + t^2)) f(q) dq}{1 - F(\bar{t})} - t\bar{t} + \frac{\lambda}{2}(t^2 + \bar{t}^2) > 0 \quad \text{for } t \in [\bar{t}, 1].$$

Differentiate the LHS of the above with respect to t :

$$\frac{\int_{[\bar{t}, 1]} (q - \lambda t) f(q) dq}{1 - F(\bar{t})} - (\bar{t} - \lambda t).$$

Note that the first term is the average of $h(q) = q - \lambda t$ in the interval $[\bar{t}, 1]$, while the second is $h(\bar{t})$. As $h(q)$ is increasing in q , the above is positive and so (15) holds for $\bar{t} \in [\frac{\lambda}{2-\lambda}, 1]$.

Next consider (14), which requires that types in $[0, \bar{t}]$ prefer to join the intermediary rather than deviate. (14) can be written as expressions (11)-(13), which, for $t = 0$, reduce to (note that $\lim_{t \rightarrow 0} R(\underline{t}/t) = \frac{2}{\lambda}t$):

$$\begin{aligned} t^2 &> 0 && \text{for } t \in \left(0, \frac{\lambda\bar{t}}{2}\right), \\ t^2 &> \frac{\int_{\bar{t}}^{\frac{\lambda\bar{t}}{2}} (tq - \frac{\lambda}{2}q^2) f(q) dq}{1 - F(\bar{t})} && \text{for } t \in \left[\frac{\lambda\bar{t}}{2}, \frac{\lambda}{2}\right], \\ t^2 &> \frac{\int_{\bar{t}}^1 (tq - \frac{\lambda}{2}q^2) f(q) dq}{1 - F(\bar{t})} && \text{for } t \in \left(\frac{\lambda}{2}, \bar{t}\right]. \end{aligned}$$

The first line is clearly true. Consider the second. Since $\frac{2}{\lambda}t < 1$, the RHS does not exceed the average of $k(q) = tq - \frac{\lambda}{2}q^2$ in the set $[\bar{t}, \frac{2\bar{t}}{\lambda}]$. $k(q)$ is a negative quadratic with its global maximum at $q = \frac{\bar{t}}{\lambda}$, which is to the left of $\frac{2\bar{t}}{\lambda}$. Therefore its maximum in $[\bar{t}, \frac{2\bar{t}}{\lambda}]$ is either at $q = \bar{t}$ or at $q = \frac{\bar{t}}{\lambda}$. Hence, a sufficient condition for the second line to hold with slack (given that $k(q)$ is not constant) is $t^2 \geq \max\left\{k(\bar{t}), k\left(\frac{\bar{t}}{\lambda}\right)\right\} =$

$\max \left\{ t\bar{t} - \frac{\lambda}{2}\bar{t}^2, \frac{\bar{t}^2}{2\lambda} \right\}$. When $t \leq \bar{t}$ the LHS of the quadratic inequality $t^2 - t\bar{t} + \frac{\lambda}{2}\bar{t}^2 \geq 0$ has no real roots for $\lambda \geq \frac{1}{2}$. Therefore for $\lambda \geq \frac{1}{2}$ the condition in the second line is always satisfied.

Finally, the third line. We have the same situation as with the second line, except that now the maximum of $k(q)$ might be reached at $q = 1$, as $\frac{t}{\lambda}$ may be greater than one. Hence, we have the additional condition: $t^2 \geq t - \frac{\lambda}{2}$, which again is guaranteed for $\lambda \geq \frac{1}{2}$.

We have thus shown that when $\lambda \geq \frac{1}{2}$ and $c = 0$, there exists a $\{0, \bar{t}\}$ -ASSE for any $\bar{t} \geq \frac{\lambda}{2-\lambda} \geq \frac{1}{3}$. The next Lemma ensures that this continues to be the case if the lower bound of the middle group, those who join the intermediary, is increased slightly.

Lemma 2 *Let $c = 0$, and let \bar{t} be such that there exists a $\{0, \bar{t}\}$ -ASSE. Then there exists $\varepsilon > 0$ such that there exists an $\{\varepsilon, \bar{t}\}$ -ASSE.*

Proof. Take a $\{0, \bar{t}\}$ -ASSE and a $\underline{t} > 0$. All types $t \in (0, \underline{t})$ will still strictly prefer not to deviate, as by symmetry and the fact that they would be on the longer side of the sub-market, they will not be matched if they join the intermediary. Types in $(\bar{t}, 1]$, will become more inclined to deviate as they now might be matched with a trader from the bottom slice. However, as we have started from a $\{0, \bar{t}\}$ -ASSE, by the continuity of payoffs in \underline{t} (due to the Lipschitz continuity of f), we can take a small enough $\underline{t} > 0$ that keeps the top types from deviating. Thus, to establish the lemma we only need to show that for some $\underline{t} > 0$, types $t \in [\underline{t}, \bar{t}]$ strictly prefer not to deviate. Since we had a $\{0, \bar{t}\}$ -ASSE, (12) and (13) are still satisfied for $\underline{t} > 0$ sufficiently small, so we only need to check that (11) holds. Rewriting it in full:

$$t^2 - \frac{\int_{\underline{t}}^{\bar{t}} \frac{1 - \sqrt{1 - \lambda^2 \frac{t}{\bar{t}}}}{\lambda} (tq - \frac{\lambda}{2}(q^2 + tt)) f(q) dq}{1 - F(\bar{t}) + F(\underline{t})} - \lambda t \underline{t} > 0 \quad \text{for } t \in \left(\underline{t}, \frac{\lambda \bar{t}^2}{2\bar{t} - \lambda \underline{t}} \right). \quad (17)$$

We first evaluate (17) at $t = \underline{t}$, which is the lower end of the range, obtaining,

$$(1 - \lambda)t^2 - \frac{1}{P(t)} \int_{tr}^t \left(tq - \frac{\lambda}{2}(t^2 + q^2) \right) f(q) dq > 0, \quad (18)$$

since $t > 0$. Recall that $r = \frac{1-\sqrt{1-\lambda^2}}{\lambda}$, and let $P(t) = 1 - F(\bar{t}) + F(t)$. Next differentiate the LHS of (18) with respect to t :

$$2(1-\lambda)t + \frac{f(t)}{P(t)^2} \int_{tr}^t \left(tq - \frac{\lambda}{2}(t^2 + q^2) \right) f(q) dq + \frac{1}{P(t)} \left\{ (1-\lambda)t^2 f(t) - r \left(r - \frac{\lambda}{2}(1+r^2) \right) t^2 f(rt) + \int_{tr}^t (q - \lambda t) f(q) dq \right\}.$$

Note that $r - \frac{\lambda}{2}(1+r^2) = 0$, and so the above is

$$2(1-\lambda)t + \frac{f(t)}{P(t)^2} \int_{tr}^t \left(tq - \frac{\lambda}{2}(t^2 + q^2) \right) f(q) dq + \frac{1}{P(t)} \left\{ (1-\lambda)t^2 f(t) + \int_{tr}^t (q - \lambda t) f(q) dq \right\},$$

which is 0 at $t = 0$. Had this been positive the proof would be complete. Instead, we need to check the second derivative:

$$2(1-\lambda) + \frac{d \frac{f(t)}{P(t)^2}}{dt} \int_{tr}^t \left(tq - \frac{\lambda}{2}(t^2 + q^2) \right) f(q) dq + \frac{2f(t)}{P(t)^2} \left\{ (1-\lambda)t^2 f(t) + \int_{tr}^t (q - \lambda t) f(q) dq \right\} - \frac{1}{P(t)} \left\{ 2(1-\lambda)t f(t) + (1-\lambda)t^2 f'(t) + t(1-\lambda) f(t) - r(tr - \lambda t) f(tr) - \int_{tr}^t \lambda f(q) dq \right\}.$$

Evaluating the above at $t = 0$:

$$2(1-\lambda) + \frac{d \frac{f(t)}{P(t)^2}}{dt} \int_{tr}^t \left(tq - \frac{\lambda}{2}(t^2 + q^2) \right) f(q) dq - \frac{(1-\lambda)t^2 f'(t)}{P(t)}.$$

or

$$2(1-\lambda) + \frac{f'(t)}{P(t)} \left\{ \frac{1}{P(t)} \int_{tr}^t \left(tq - \frac{\lambda}{2}(t^2 + q^2) \right) f(q) dq - (1-\lambda)t^2 \right\}.$$

The requirement that f be Lipschitz continuous at 0 implies that $f'(0)$ is finite, and therefore the above is $2(1-\lambda) > 0$ at $t = 0$. Hence, the LHS of (18) is convex, which establishes the Lemma. ■

The Lemma implies that, whenever both $\{0, \bar{t}\}$ and $\{\varepsilon, \bar{t}\}$ are ASSEs, in the latter equilibrium all the joining players strictly prefer to join the intermediary, as their equilibrium payoff is the same but their deviation payoff is lower. Consequently,

there is a sufficiently small $c_\varepsilon > 0$ such that $\{\varepsilon, \bar{t}\}$ is an ASSE when the joining fee is c_ε or less. This establishes the Proposition. ■

This existence result holds regardless of the distribution of types, f ,¹⁶ and is therefore very general. However it clearly does not characterise fully the set of sandwich equilibria: as intuition suggests, and the technique of the proof confirms, there is a rich multiplicity of sandwich equilibria:¹⁷ specifically, the set of sandwich equilibria has, generically, full dimensionality in the set of possible values of \underline{t} and \bar{t} , $\{\underline{t}, \bar{t} \in [0, 1] \mid \underline{t} < \bar{t}\}$.¹⁸ Intuitively, sandwich equilibria exist if a number of incentive constraints are satisfied, and the proof of Proposition 3 shows that it is possible to select $\{\underline{t}, \bar{t}\}$ such that all these constraints are slack at the $\{\underline{t}, \bar{t}\}$ -sandwich equilibrium. This implies that the set of sandwich equilibria contains $\{\underline{t}, \bar{t}\}$ -sandwich equilibria which have the property that there exists ε such that for every $\{\underline{v}, \bar{v}\}$ satisfying $|\underline{t} - \underline{v}| + |\bar{t} - \bar{v}| < \varepsilon$ there is also a $\{\underline{v}, \bar{v}\}$ -sandwich equilibrium. This can be interpreted as giving our equilibrium

¹⁶The requirement that f be Lipschitz continuous at 0 is a sufficient condition, which is used to prove existence, but is not necessary: sandwich equilibria exist even when the condition is violated.

¹⁷The defining feature of a sandwich equilibrium is that the “top” and the “bottom” traders do not join the intermediary: this feature is in contrast to the “threshold” equilibria identified by the literature, where the highest types join the intermediary. There might also exist more complex equilibria, for example, sandwiches with three slices: the unit segment is divided in five intervals, such that type in the first, third and fifth stay out and those in the second and fourth interval join the intermediary: in this case the middle interval has a “hole”, that is there are types in $[\underline{t}, \bar{t}]$ who do not join the intermediary. This is analogous to Bloch and Ryder’s (2000) finding that there might be threshold equilibria where there are “holes” in the distribution of joiners (Theorem 3.5, p 107). This can only happen if the intermediary charges a proportional commission, not, as here, a flat fee. We also conjecture that there exist asymmetric sandwich equilibria, where the intervals of joiners are different on the two sides of the market, though their measure is the same.

¹⁸In Section 4.5, we use computer simulations to provide a full characterisation of the set of sandwich equilibria, for specific values of the two parameters and restricting attention to the uniform distribution.

set a degree of robustness to the introduction of small errors in the matching technology available to the intermediary. Suppose, for example, that matching through the intermediary is perfectly assortative with probability $(1 - \varepsilon)$, and random with probability ε , with $\varepsilon > 0$ and “small”. This would reduce slightly the benefit of joining the intermediary, given in (6), (8) and (10), and therefore make a deviation slightly less attractive for types in $(\bar{t}, 1]$, and slightly more attractive for types in $[0, \underline{t})$. Conversely, it would make following the equilibrium strategy slightly more (less) attractive for types below (above) the average of the types in $[\underline{t}, \bar{t}]$. Except at the boundary of the set of sandwich equilibria, a sufficiently small ε would not prevent a pair $\{\underline{t}, \bar{t}\}$ from being a sandwich equilibrium.

The “robust” nature of sandwich equilibria may suggest that they are somewhat easy to obtain. This, however, is definitely not the case: existence of sandwich equilibria is subject to quite stringent conditions. These conditions illustrate the crucial role played by the continuation value, which must be such that higher types have a better outside option, and therefore also provide the intuitive reason for the emergence of sandwich equilibria. The following proposition establishes this formally.¹⁹

Proposition 4 *If the continuation value is constant across types, then there are no sandwich equilibria.*

Proof. Let the discounted value of the common option be denoted by $\ell > 0$, the same for all traders. We prove the Proposition by contradiction. Suppose therefore that there does exist a sandwich equilibrium. Let x be the supremum of types who join the intermediary at this equilibrium. Then, for any $y > x$, the following two

¹⁹Damiano and Li (2007, p. 260) conjecture that type dependent reservation utilities would not alter the “threshold” structure of the equilibria. Our paper can therefore be seen as limiting the applicability of this conjecture.

inequalities must hold:

$$x^2 - c \geq xE[v|xv \geq \ell] \Pr(xv \geq \ell) + \ell \Pr(xv < \ell), \quad (19)$$

$$yE[v|yv \geq \ell] \Pr(yv \geq \ell) + \ell \Pr(yv < \ell) \geq yx - c. \quad (20)$$

The probabilities and expectations on the RHS of (19) and on the LHS of (20) are taken relative to the distribution of types who do not join in equilibrium. The LHS of both (19) and (20) is the equilibrium payoff: (19) requires that type x , who joins the intermediary and receives payoff $x^2 - c$, is better-off than at her outside option, otherwise she would not join. If she does not join, trade takes place if $2yv - 2\ell \geq 0$, splitting the gross surplus equally; otherwise she collects her outside option, ℓ . The RHS in (19) and (20) is the deviation payoff: if the type who joins were to deviate, she would be randomly matched with a non-joiner and would save the fee. Vice versa, if a type who should not join in equilibrium decided to join instead, she would pay the fee and be assortatively matched with a trader on the other side, whose type will be arbitrarily close to x , the supremum of the joiners. As $y > x$, either trade occurs, giving y the payoff in the inequality or it is y who refuses to trade to obtain an even higher payoff.

Rearranging inequalities (19) and (20), we have

$$\begin{aligned} x^2 - xE[v|xv \geq \ell] \Pr(xv \geq \ell) - \ell \Pr(xv < \ell) &\geq c \\ &\geq yx - yE[v|yv \geq \ell] \Pr(yv \geq \ell) - \ell \Pr(yv < \ell). \end{aligned} \quad (21)$$

Next, note that

$$xE[v|xv \geq \ell] \Pr(xv \geq \ell) + \ell \Pr(xv < \ell) \geq xE[v|yv \geq \ell] \Pr(yv \geq \ell) + \ell \Pr(yv < \ell).$$

This holds because the LHS is type x 's optimal deviation payoff, while the RHS assumes that (following a deviation) sometimes x trades even if it gives her less than her outside option.

Hence a necessary condition for (21) to hold is that

$$\begin{aligned} x^2 - xE[v|xv \geq \ell] \Pr(yv \geq \ell) - \ell \Pr(yv < \ell) &\geq c \\ &\geq yx - yE[v|yv \geq \ell] \Pr(yv \geq \ell) - \ell \Pr(yv < \ell), \end{aligned}$$

or

$$(x - y) (x - E[v|yv \geq \ell] \Pr(yv \geq \ell)) \geq 0. \quad (22)$$

Note that, by (21), $x - E[v|xv \geq \ell] \Pr(xv \geq \ell) \geq \frac{\ell \Pr(xv < \ell) + c}{x} > 0$. Thus if we can show that there exists $y > x$ such that $E[v|yv \geq \ell] \Pr(yv \geq \ell) - E[v|xv \geq \ell] \Pr(xv \geq \ell) < \frac{\ell \Pr(xv < \ell) + c}{x}$, then $x - E[v|yv \geq \ell] \Pr(yv \geq \ell) > 0$ and hence (22) implies a contradiction. Such a y indeed exists because – by construction – all types between x and y do not join the intermediary; since the type distribution contains no mass points, $E[v|yv \geq \ell] \Pr(yv \geq \ell)$ is continuous in y , so $E[v|yv \geq \ell] \Pr(yv \geq \ell) - E[v|xv \geq \ell] \Pr(xv \geq \ell)$ converges continuously to 0 as y tends to x . ■

The logic underlying this result is that a uniform outside option has no effect on the outcome of bargaining; the gross surplus is divided equally between the parties. This is exactly the same as if utility were non-transferable: our paper therefore shows that transferability of utility is necessary for sandwich equilibria to exist. Intuitively, the fifty-fifty arrangement implied by uniform continuation value or non-transferable utility makes meeting high types very attractive, and thus puts an upper bound on the relative probability of meeting a high type if not joining the intermediary. On the other hand, this very fifty-fifty split also makes meeting low types not very attractive, because they will have a good deal of bargaining power. To keep high types from joining the intermediary the relative probability of meeting a low type if not joining the intermediary must be low. With uniform continuation values, these two requirements cannot be simultaneously met. To alter the constraints so as to make them compatible with each other, the bargaining outcome needs to favour the higher types. Having a continuation value which is increasing in the type does just that.

4 Discussion

4.1. We have assumed perfect information: upon meeting, the traders can observe each other's type. Imperfect observability would generate asymmetry

of information and give rise to a potential for signalling. The decision whether or not to join the intermediary conveys some information, and thus it affects a trader's payoff not just because it affects the range of potential partners, but also because it affects the partner's beliefs about one's type. Analysis of a model which incorporates both asymmetric information and the possibility of joining an intermediary is likely to be beyond tractability. Interestingly, in a pure signalling set-up, Feltovich et al. (2002) show that there can be equilibria with non-monotone signalling strategies, known in the literature as counter-signalling. In these equilibria, only middle types send the costly signal, while low types and high types pool by not sending it.²⁰ The analogy with the outcome of our model suggests that, in situations where there is a binary choice (join the intermediary or send the signal), non-monotonicity of the equilibrium strategies in type is a common outcome (Renou, 2010, is another example).

4.2. Some of the existing literature (e.g. Yavaş, 1994, Bloch and Ryder, 2000) considers a fee proportional to the benefit from trade, as is the case when the intermediary charges a commission. Charging a commission has of course a much higher information requirement than a flat fee, and in fact in many markets (online dating, mortgage brokering and shopping centres are examples) the fee charged is flat. A second reason why we have chosen to model the case of a flat fee is that it makes our result stronger, as a proportional commission makes the existence of sandwich equilibria *easier*: with a flat fee, when middle types join, it is certainly the case that the high types will not forgo intermediation due to its cost, which may happen with a proportional commission. Finally, note

²⁰As an example, suppose there are three types, $H > M > L$, and the signal is binary. Suppose that H types are much more likely to be associated with one signal while L types with the other, while M types are associated with either with equal probability. In such a situation, H is sufficiently confident that she will be told apart from L and hence she is more interested in distinguishing herself from M . As M is signalling to distinguish himself from L , the way for H to be different is by not signalling.

that the existence of non-degenerate sandwich equilibria is not due to the flat fee excluding the lower quality segment from intermediation, since our result holds for zero fee.

4.3. We assume that the intermediary does not choose the fee strategically (unlike, among others, Damiano and Li, 2007). The main purpose of this paper is to show the possibility that sandwich equilibria might exist. The fee could simply reflect the cost, as it would be the case with a welfare maximising intermediary (or with sufficiently intense competition among intermediaries). On the other hand, in the presence of multiple equilibria it is not straightforward how to identify the best strategy for a profit maximising intermediary. As the example in 4.5 shows, sandwich equilibria exist only for small fees, while threshold equilibria exist for higher fees too. Imagine, for example, that the intermediary would like to raise the price in order to move from a sandwich equilibrium to a more profitable threshold equilibrium. It is unlikely that the top players, who do not join, would at some price high enough decide instead to do so.

4.4. A further assumption we made is that the intermediary has access to a perfect matching technology, whereas trading in the direct market gives rise to perfectly random matching. In practice, of course, both are approximations. Relaxing them has in general an ambiguous effect on the attractiveness of using the intermediary. On the one hand, real world trading in the direct market is far from random: for example, high quality singles who do not join a lonely heart agency but choose to search by patronising nightclubs are much more likely to meet a high quality potential partner, since the choice of nightclubs or similar venues is clearly not random: dress codes, bouncers, high prices for drinks are all imperfect substitutes for membership fees. This reduces the opportunity cost of not joining, reducing further the non-joiners' incentive to join. Moreover, if the intermediary has access to a technology less perfect

than what we have assumed here, then again joining it clearly becomes less attractive. A countervailing tendency is the fact that, while we have assumed that matching occurs with probability 1 both through the intermediary and in the direct market, in practice the frequency of matches would be lower in the direct market.

An important insight of our analysis is that a technological advantage by the intermediary is a necessary condition for the existence of sandwich equilibria. To see this, suppose that matching through the intermediary is in fact random. In this case, for $c = 0$, there is a unique sandwich equilibrium:²¹ this is given by the condition that the average type is the same in the direct and the intermediated markets. But now consider a strictly positive fee, $c > 0$. Because of supermodularity, different types would be indifferent at different differences in averages, so only threshold equilibria can exist.

4.5. A natural question of interest is the shape and size of the set of sandwich equilibria. This matters because, if it turned out in practice that any sandwich equilibrium is arbitrarily close to a threshold equilibrium, which is a degenerate $\{\underline{t}, 1\}$ -sandwich equilibrium, then our analysis would not be able to explain the observed regularity which motivate it, that “a lot” of top traders do not use intermediation. While characterising in general the set of sandwich equilibria is hard, a simple example suffices to address this question. In Figure ??,²² we illustrate the entire set of sandwich equilibria in the special case of a uniform density function for v and q , that is when $f(t) \equiv 1$. The two diagrams depict the lower portion of $[0, 1]^2$ (note that the diagonal is not a 45 degree line, as the axes are drawn in different scales). The highlighted regions are the sets

²¹Provided we maintain the assumption of assortative matching in the second period.

²²The appendix (available on request or at sites.google.com/site/giannidefraja/) provides details of how the pictures have been obtained. In essence, it was a “brute force” process: given \underline{t} and \bar{t} we checked that no trader in $[0, 1]$ had an incentive to deviate, and repeated the procedure on a fine grid, checking for every possible pair of points (\bar{t}, \underline{t}) below the diagonal.

of sandwich equilibria for two values each of c and λ . In both diagrams, the shaded (respectively outlined) area represents combinations of points (\bar{t}, \underline{t}) such that a $\{\underline{t}, \bar{t}\}$ -sandwich equilibrium exists when $c = 0$ (respectively $c = .0005$).

For $c = 0$ and $\lambda > 1/2$, the set of sandwich equilibria is drawn on the RHS of Figure 3: the lower contour of the set is the set of points on the horizontal axis between a critical value of \bar{t} and 1; the upper contour of the sandwich equilibrium set is a locus strictly above 0 for $\bar{t} < 1$, which tends to 0 as \bar{t} tends to 1. When c is positive, clearly there cannot be equilibria where the lowest types join the intermediary: they simply cannot afford the fee. Note the “multiplier” effect of the fee: the types just below the lowest type who join are not deterred from joining by the fee, which is but a tiny fraction of their valuation. The relatively high lower bound is needed in equilibrium as, if there were too few low types joining, then the highest types who should join the intermediary would prefer to deviate as they would be likely to be matched with types from the upper end of the distribution. The multiplier effect implies that highest value of c such that sandwich equilibria exist is “very low”, the intermediation fee must be small, compared to the average or median valuation.

In the diagram threshold equilibria are represented by points on the vertical segment joining $(1, 0)$ and $(1, 1)$. By Proposition 2, all points on a vertical segment with its lower end at $(1, 0)$ are threshold equilibria, and, for $c = 0$, by Corollary 2 the set of threshold equilibria is the entire segment joining $(1, 0)$ and $(1, 1)$. Note therefore that, for $c = 0$, the equilibrium set (the union of the set of sandwich and of threshold equilibria) is connected for high λ and disconnected for low λ . Numerical simulations suggest that, for the uniform density case we considered the cut-off value of λ is $\frac{1}{2}$. As Proposition 3 gives sufficient conditions, it is not surprising that there exist sandwich equilibria for $\lambda < 1/2$ as well. Note that, as shown in Figure 3, in the low λ case, \bar{t} can be very low, and even for λ high there are sandwich equilibria where no

trader above the median uses the intermediary. For $c = 0$ sandwich equilibria, unlike threshold equilibria, are “rare”, suggesting that a simple “coordination equilibrium” story is not all is needed to explain their emergence.

5 Concluding remarks

This paper contributes to our understanding of markets where intermediaries are active but traders may also choose to trade unassisted.

Stylised facts indicate that trader behaviour may be non-monotone. For example, consider the role of education in the marriage market: the widespread evidence of assortative education matching (for example, Blossfeld and Timm, 2003) indicates that education is a supermodular characteristic: more educated individuals value it more. With this in mind, consider the diagram in Figure 4. It is an illustration derived from the dataset constructed by Hitsch et al (2010). They study the link between mate preference and match formation, and report data on the education level of internet users at large and a representative sample of the members of a major online dating service provider in San Diego and Boston. In the picture, we choose convenient thresholds in their ranking to determine three groups. The figure plots the percentage of internet users belonging to each group who have joined the dating service. The diagram suggests a non-monotonic relation between “type” and the propensity to join the intermediary: those with intermediate education levels are considerably more likely to use the online provider than types with higher or lower education.²³

In this paper we have rigorously established that this non-monotone be-

²³The diagram is only suggestive, as clearly only a small fraction of the internet users are looking for a partner in the period considered. It seems plausible that the likelihood of being looking for a partner is roughly independent of education. In this case, if we conditioned the joining probabilities on actually being looking for a partner, the height of each bar would increase roughly proportionally, and their relative size would not change.

haviour, where the traders who have the most to gain from using the superior matching mechanism provided by the intermediary choose not to use it, may indeed form part of an equilibrium. The existence of such “sandwich” equilibria, however, is subject to the strong condition that the traders’ continuation value is sufficiently increasing in their type. Consequently the intertemporal characteristics of each market determine whether or not sandwich equilibria can exist: high type traders have most to gain from trade now, this must continue to be the case if they choose to delay trade.
